Abstract

To reduce unproductive picker walking in traditional picker-to-parts warehousing systems, automated guided vehicles (AGVs) are used to support human order pickers. In an AGV-assisted order picking system, each human order picker is accompanied by an AGV during the order picking process. AGVs receive the picked items and, once a picking order is complete, autonomously bring the collected items to the shipping area. Meanwhile, a new AGV is requested to meet the picker at the first storage position of the next picking order. Thus, the picker does not have to return to a central depot but continuously picks order after order. This paper addresses both the routing of an AGV-assisted picker through a single-block parallel-aisle warehouse and the sequencing of incoming orders. We present an exact polynomial time routing algorithm for the case of a given order sequence, which is an extension of the algorithm of Ratliff and Rosenthal (1983), and a heuristic for the case in which order sequencing is part of the problem. In addition, we investigate the use of highly effective TSP solvers that can be applied after a transformation of both problem types into a standard TSP. The numerical studies address the performance of these methods and study the impact of AGV usage on picker travel: by using AGVs to avoid returns to the depot and by sequencing in (near-)optimal fashion, picker walking can be reduced by about 20% compared to a traditional setting. Sharing AGVs among the picker workforce enables a pooling effect, so that in larger warehouses only about 1.5 AGVs per picker are required to avoid picker waiting.

1 Introduction

More than 80% of all warehouses in Western Europe still follow the traditional picker-to-parts setup (see Napolitano 2012). In such warehouses, stock keeping units (SKUs) are stored in low-level racks, and human order pickers collect requested items by traveling from shelf to shelf. While, on the positive side, the investment costs for this setup are low, the biggest disadvantage is certainly the large fraction of unproductive picker walking time. The latter is frequently cited to consume 50% and more of the pickers' working hours in a typical picker-to-parts warehouse (Tompkins et al. 2003, de Koster et al. 2007). In recent years, especially triggered by the steadily increasing sales volumes of e-commerce (Statista 2019), many alternative warehousing concepts have been developed to increase the efficiency of order picking. These concepts, which are systematically reviewed by the recent survey papers of Azadeh et al. (2019), Boysen et al. (2019), and Van Gils et al. (2018), reach from adaptations of the traditional picker-to-parts setup, e.g., batching, zoning and sorting as well as mixed-shelves storage, to automated parts-to-picker solutions. The novel concept treated in this paper belongs to the former group: the human order pickers of the traditional picker-to-parts setup are supported by automated guided vehicles (AGVs).

1.1 AGV-assisted order picking

In AGV-assisted order picking, human order pickers are accompanied by AGVs while collecting the items requested by the current picking order at their respective storage positions. The picker puts the collected items into a bin, container, or roll cage (if large-sized SKUs are processed) carried by the AGV. Once a picking order is complete, the AGV autonomously returns to the depot with the collected items, while the picker remains in the storage area. A new AGV is requested to meet the picker at the first storage position of the next picking order. This concept has the following advantages:

- *Reduced walking*: Pickers can continuously pick order after order without intermediate returns to the depot. This increases the pick density per picking tour and reduces the pickers' unproductive walking. It is one of the main intentions of this paper to quantify this positive effect.
- *Easy implementation*: Adding AGVs to an existing picker-to-parts system barely alters the basic fulfillment processes. Consequently, AGV-assisted picking can quickly be implemented without much organizational overhead.
- *Scalability*: By adding additional pickers and AGVs (or by removing them), the concept can quickly be adapted to varying workloads, e.g., when the number of picking orders increases during end-of-season sales. Other concepts based on fixed hardware (e.g., conveyors, automated storage systems or sorters) are not that flexible.

On the negative side, investment costs for the AGVs have to be considered. However, AGVs are a long-established and standardized technology, so that the investments costs are often not overly large, and many warehouses require AGV support anyway, especially if large pick lists, e.g., due to batching, or heavy and bulky items need to be handled. In these cases, updating the existing AGV fleet to capacitate them for AGV-assisted picking generally comes with acceptable additional costs (Boysen et al. 2019). Consequently, most applications of AGV-assisted picking are reported for warehouses handling white goods, home electronic equipment, and carpets (Boysen et al. 2019). However, AGV-assisted picking is not bound to heavy and bulky items; Figure 1 depicts an AGV that handles multiple order bins for small-sized items.

1.2 Decision problems and literature review

AGV-assisted picking is a relatively new concept, and, to the best of our knowledge, this paper is the first to address it. This statement is supported by the recent survey papers of Azadeh et al. (2019) and Boysen et al. (2019), which both mention *Pick Support AGVs* as an important, yet unexplored technology. Therefore, we briefly summarize the main decision problems related to this concept (Boysen et al. 2019):

- *Setup*: The most critical decision when setting up an AGV-assisted picking system is the sizing of the AGV fleet. To save investment costs, the fleet should be as small as possible. However, if the fleet is too small and pickers frequently have to wait for an AGV, the reduced walking does not translate into a better picking performance. Obviously, one picker per AGV is the lower bound for a reasonable fleet size when introducing AGV-assisted order picking. A straightforward heuristic solution is to equip each picker with two AGVs. This allows one AGV to return the previous picking order to the depot and then continue to the first storage position of the subsequent picking order, while the other AGV accompanies the processing of the current order. Except for uncommon warehouse layouts with excessive distances from the depot, two AGVs per picker are thus likely to avoid picker idle time very reliably. In Section 6.4, however, we show that the pooling effect when sharing AGVs among a larger picker workforce allows to considerably reduce the AGV-per-picker ratio.
- *Storage assignment*: To reduce walking distances, traditional storage assignment policies (e.g., class-based storage or full turnover storage (see de Koster et al. 2007)) assign frequently requested SKUs storage space close to the depot. In AGV-assisted picking, however, pickers remain in the storage area, so that locating frequently requested SKUs rather in the center of the warehouse, where they are quickly accessible, seems a valid idea. Exploring this policy and deriving further storage policies for AGV-assisted picking is an interesting field for future research. In our research, we assume a given storage assignment of SKUs.
- *Order batching*: Picking orders need not be identical with customer orders. Especially, if customer orders are small and only contain a few order lines each comprising just a few items, a batching of customer orders to larger picking orders can increase the pick density per tour and thus increase picking performance. Figure 1, for instance, depicts an AGV where six customer orders, each associated with a separate bin to avoid an additional order consolidation after picking, are unified to a single picking order. More details on order batching are, e. g., provided by the survey paper of Henn et al. (2012). In this paper, we presuppose that order batching has been completed and assume given picking orders.
- *Picker routing*: Given a set of picking orders assigned to a picker, the picker routing problem decides

the processing sequence of orders and the picker tour along the storage positions defined by each picking order with the goal of minimizing travel distance or travel time. In traditional picker-to-parts warehouses with a central depot and without AGV support, the order sequence does not impact the walking distance of a picker; the problem decomposes into separate problems for each picking order. The seminal paper of Ratliff and Rosenthal (1983) has shown that the resulting traveling salesman problem (TSP) can be solved in polynomial time in a single-block parallel-aisle warehouse, in which the SKUs are stored in racks along both sides of multiple parallel picking aisles that are enclosed by a storage-free cross aisle at the top and at the bottom (see Figure 2a). This result has been extended to parallel-aisle warehouses with a middle cross aisle (see Figure 2b) by Roodbergen and de Koster (2001). Recently, Pansart et al. (2018) have introduced an exact picker routing algorithm whose run-time increases exponentially only in the number of cross aisles. Goeke and Schneider (2018) present effective modeling approaches for the single-block case, also considering extensions like scattered storage, decoupling of picker and cart, and multiple end depots. De Koster and van der Poort (1998) study an extension in which the picker tour is allowed to start and end at the bottom end of any picking aisle, and start and end point do not have to coincide. Vis and Roodbergen (2009) investigate the routing of straddle carriers in a container terminal. Here, the start point of the tour is assumed to be given whereas the end point can be freely selected. Both start and end point of the tour must be located at the top or bottom end of a picking aisle.

In AGV-assisted order picking, the picker processes order after order without intermediate returns to the depot. Thus, the resulting picker routing problem does not decompose into separate problems, and we have to determine the optimal order sequence and the picker tour to collect all items of the picking orders in the given sequence. This problem corresponds to the clustered TSP (CTSP, Chisman 1975), which is an extension of the TSP in which the cities are partitioned into clusters, and the salesman has to visit the cities of each cluster consecutively. The cities of the CTSP are our picking positions, and the clusters correspond to picking orders. The CTSP is a well-researched standard problem, for which many well-performing solution procedures exist (see, e.g., Jongens and Volgenant 1985, Guttmann-Beck et al. 2000, Bao and Liu 2012, Mestria 2018).

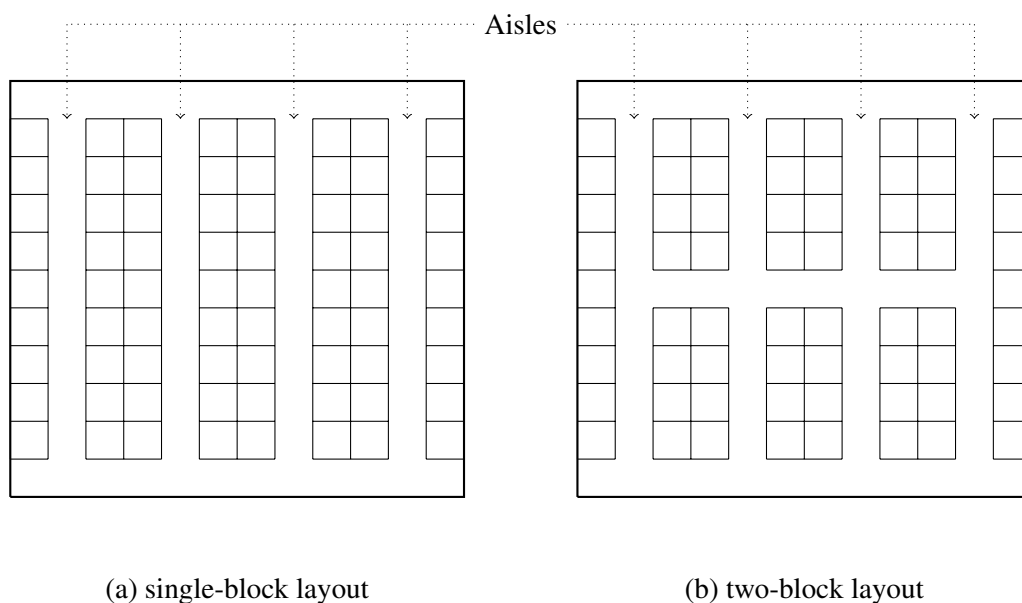

Figure 2: Parallel-aisle warehouses with and without intermediate cross aisle.

1.3 Contributions and structure of the paper

This paper investigates the picker routing problem of a single order picker in a single-block parallel-aisle warehouse with AGV support. We are given a set of picking orders, each containing a set of SKUs defining the requested items. Because we assume that each SKU is stored at a given dedicated storage position, a picking order consists of a set of picking positions that have to be visited. A feasible picker tour visits the picking positions of all picking orders and respects the order sequence, i.e., picking positions belonging to the same order have to be visited in direct succession, so that each AGV is loaded with a unique picking order. Among all feasible picker tours, we seek one that minimizes the total travel distance of the picker. For classical picker-to-parts systems (i.e., without picker idle time while waiting for late AGVs), the travel time is an increasing function of the travel distance, so that minimizing the latter is considered as a primary objective in warehouse design and optimization (de Koster et al. 2007). The same is true for an AGV-assisted system with an adequately sized AGV fleet, and therefore we use the same objective function. The resulting optimization problem can be modeled as a CTSP (see Section 2), which—as a generalization of the TSP—is well-known to be strongly NP-hard.

However, in parallel-aisle warehouses, which are prevalent in practice, only very specially structured distance matrices occur, so that the general CTSP, which assumes arbitrary distance matrices, is needlessly general, and the respective algorithms are unnecessarily complex. For a better distinction, we use the term general CTSP (GCTSP) if we assume arbitrary distance matrices, and the term warehouse CTSP (WCTSP), if we assume the distance matrices arising in parallel-aisle warehouses. We further distinguish CTSPs with given cluster sequence (abbreviated as GCTSP-GCS and WCTSP-GCS, respectively), where the order in which clusters must be visited is given, and CTSPs with open cluster sequence (abbreviated as GCTSP-OCS and WCTSP-OCS, respectively), in which the order in which clusters are visited is a decision. Note that CTSPs with given cluster sequence are important optimization problems in many warehouses. Timely fulfilling customer demands is among the top priorities in most warehouses, so that customer orders are often prioritized according to increasing due dates. Once such a sequence of customer orders exists, picker routing corresponds to solving a CTSP with given cluster sequence.

It is well known that the GCTSP-GCS is already strongly NP-hard (see, e.g., Potvin and Guertin 1998). In this paper, we show that the WCTSP-GCS in a single-block parallel-aisle warehouse—we will refer to this problem as single-block WCTSP-GCS in the following—is polynomially solvable by means of a dynamic programming (DP) approach (Section 3). Indeed, analogous to the TSP in traditional picker-to-parts systems with a central depot, the special parallel-aisle structure of warehouses simplifies the problem. Inside the DP, we have to find optimal tours for picking the items of one cluster for a given start and end point of the tour (that do not have to coincide). Consequently, the algorithm of Ratliff and Rosenthal (1983) cannot be directly used because the authors assume that the start and end point represent the same location, namely the depot. Therefore, we develop a dedicated method for the more general case of arbitrary start and end points, which extends the algorithm of Ratliff and Rosenthal (1983), see Section 4. Note that it is not possible to mimic this algorithm by applying the original algorithm of Ratliff and Rosenthal (1983) to a problem instance with modified distance matrix because by modifying the matrix the special structure required for the application of the algorithm of Ratliff and Rosenthal (1983) is destroyed. Also note that this case is not covered by the algorithms presented in de Koster and van der Poort (1998) or Vis and Roodbergen (2009). In addition, we show how the widespread heuristic routing strategies S-shape and largest-gap (see, e.g., de Koster et al. 2007) can be modified to handle the more general case of given start and end point. Solving the WCTSP-GCS in two-block parallel-aisle warehouses (see Figure 2b) requires an analogous extension of the polynomial time routing procedure of Roodbergen and de Koster (2001), which we leave to future research.

In Section 5, we prove that the single-block WCTSP with open cluster sequence (WCTSP-OCS)—and also the two-block WCTSP-OCS) are strongly NP-hard. We embed the DP for solving the single-block WCTSP-GCS within a greedy heuristic to solve the single-block WCTSP-OCS. Section 6 explores the computational performance of our algorithms using traditional GCTSP solution methods (based on transformations to the standard TSP) as comparison methods. Special emphasis is put on comparing the resulting walking distances with and without AGV support. In this way, warehouse managers can assess the tradeoff between additional investment costs into AGVs and the reduced walking distances. In our problem setting, we presuppose that AGVs are no bottleneck resource. Thus, we assume that an AGV is always available if required, and no picker has to wait for an AGV arriving late. Ensuring this comes at the price of additional AGVs. However, we show that the pooling effect when sharing AGVs among several pickers allows to considerably reduce the fleet size (Section 6.4). Finally, Section 7 concludes the paper.

2 Problem description and notation

This section formally describes the AGV-assisted picker-routing problem assuming general warehouse layouts and introduces the required notation. We present formulations for the GCTSP-OCS (Section 2.1) and the GCTSP-GCS (Section 2.2). Section 2.3 shows how GCTSP instances can be transformed into standard TSP instances, which allows to solve them using highly effective TSP methods.

2.1 General CTSP with open cluster sequence

Given $k = 1, \dots, l$ picking orders P_k each defining the set of picking positions where the SKUs requested by the respective order are stored. We denote with $m = \sum_{k=1}^l |P_k|$ the total number of required picking positions and with P the set of all picking positions to be visited including position 0 representing the start and end point of the picking tour, i.e., $P = \bigcup_{k=1, \dots, l} P_k \cup \{0\}$. Position 0 can refer to the depot or any other position in the warehouse, e.g., a rest area. To make the presentation of the paper concise, we refer to position 0 as the depot throughout the remainder of the paper. Multiple picking orders may request the same SKU, so that a picking position may have to be visited multiple times. Each of these individual visits has an identity (i.e., a specific order it belongs to) and is therefore contained in P . For any pair of picking positions j and j' , we know the walking distance $d_{jj'}$ between them. We seek a tour starting and ending at the depot 0 and visiting all required picking positions in a way that picking positions belonging to an order P_k are picked in direct succession and the length of the tour is minimal.

Table 1: Notation

l	number of picking orders
P	set of all required picking positions (with $P = \{0, 1, \dots, m\}$ including the depot 0)
P_k	set of picking positions of picking order k
$d_{jj'}$	walking distance between picking positions j and j'
$x_{jj'}$	binary variable: 1, if position j' is visited directly after position j ; 0, otherwise
u_j	continuous variable: sequence position of picking position j

Using the notation summarized in Table 1, a mixed-integer program (MIP) for the GCTSP-OCS can be formulated (see, e.g., Mestria 2018):

$$\text{GCTSP-OCS: Minimize } \sum_{j \in P} \sum_{j' \in P} d_{jj'} \cdot x_{jj'} \quad (1)$$

subject to

$$\sum_{j \in P} x_{jj'} = 1 \quad \forall j' \in P \quad (2)$$

$$\sum_{j' \in P} x_{jj'} = 1 \quad \forall j \in P \quad (3)$$

$$\sum_{j \in P_k} \sum_{j' \in P_k} x_{jj'} = |P_k| - 1 \quad \forall k = 1, \dots, l \quad (4)$$

$$u_{j'} - u_j \geq m \cdot x_{jj'} - m + 1 \quad \forall j, j' \in P \setminus \{0\} \text{ with } j \neq j' \quad (5)$$

$$u_0 = 0 \quad (6)$$

$$1 \leq u_j \leq m \quad \forall j \in P \setminus \{0\} \quad (7)$$

$$x_{jj'} \in \{0, 1\} \quad \forall j, j' \in P \quad (8)$$

Objective function (1) minimizes the total travel distance. Constraints (2) and (3) assign each picking position exactly one predecessor and one successor, respectively. All picking positions belonging to the same order have to be picked in direct succession, which is ensured by (4). The well-known Miller-Tucker-Zemlin constraints defined by (5), (6), and (7) eliminate subtours of the picker (Miller et al. 1960), and finally, (8) defines the binary variables.

2.2 General CTSP with given cluster sequence

For adapting the MIP presented in Section 2.1 to the GCTSP-GCS, constraints (4) are replaced with

$$x_{jj'} \leq \sum_{k=1}^{l-1} a_{jk} \cdot (a_{j'k} + a_{j'k+1}) + a_{jl} \cdot a_{j'l} \quad \forall j, j' \in P \setminus \{0\} \text{ with } j \neq j', \quad (9)$$

where a_{jk} is a binary parameter having value 1 if picking position j is to be visited during processing the k -th picking order (0 otherwise). This leads to $m(m-1)$ additional constraints. To reduce the number of additional constraints to m , the following constraints can be used instead of constraints (9)

$$\alpha_k \leq u_j \leq \omega_k \quad \forall k = 1, \dots, l; j \in P_k, \quad (10)$$

where $\alpha_k = \sum_{k'=1}^{k-1} |P_{k'}| + 1$ ($\omega_k = \sum_{k'=1}^k |P_{k'}|$) is the first (last) sequence position that is valid as a picking position of order k . Alternatively, we can simply set all distances $d_{jj'}$ for all $j \in P_l, j' \in P_k$ with $l > k$ or $l + 2 \leq k$ to a prohibitively high value, so that only cluster changes among adjacent clusters are enabled. With these adapted distances the MIP for the GCTSP-OCS can directly be applied without (9) or (10).

Both GCTSPs are challenging optimization problems and suitable algorithms considering the general structure are listed in Section 1.2. The best performing solution methods rely on a transformation of the CTSP into a standard TSP, which is solved by means of high-performance TSP methods. Thus, we also follow this path and explain the instance transformations that are used by the state-of-the-art solution methods in the following section.

2.3 Transformation from GCTSP to TSP

Because the standard TSP is one of the most researched problems in the field of Operations Research, highly effective solution methods exist. In this section, we present transformations from both the GCTSP-OCS and

GCTSP-GCS to the TSP, which enable us to apply TSP methods to solve GCTSP and WCTSP instances (see also Chisman 1975, Helsgaun 2014). In the following, M is a sufficiently large number (greater than the maximum distance in the respective instance). Because we are only interested in solving WCTSP instances, which feature symmetric distances, we assume the distance matrix $d_{jj'}$ of the GCTSP instance to be symmetric. The transformations are designed to produce symmetric TSP instances because the state-of-the-art exact TSP solver used in our numerical experiments is only able to solve symmetric TSP instances.

GCTSP-OCS \rightarrow TSP: We can transform a GCTSP-OCS instance to a TSP instance with $|P|$ vertices and distance matrix $d'_{jj'}$ with $j, j' \in P$ as follows:

$$d'_{jj'} := \begin{cases} d_{jj'}, & \text{if } j \text{ and } j' \text{ are in the same cluster,} \\ d_{jj'} + M, & \text{otherwise.} \end{cases} \quad (11)$$

In the above definition, all edges between vertices from different clusters are penalized with a value of M , so that in an optimal solution all nodes in a cluster are visited consecutively. Recall that the GCTSP includes one cluster for every order P_k and one additional cluster for the depot 0 ($l + 1$ in total). Therefore, the objective value of a solution to the TSP instance is smaller than $(l + 2) \cdot M$ if and only if it is a feasible GCTSP solution. In this case, a value of $(l + 1) \cdot M$ must be subtracted from the objective value of the TSP solution to obtain the objective value of the corresponding GCTSP solution.

GCTSP-GCS \rightarrow TSP: A GCTSP-GCS instance can be transformed into a TSP instance with $|P|$ vertices and distance matrix $d'_{jj'}, j, j' \in P$:

$$d'_{jj'} := \begin{cases} d_{jj'}, & \text{if } j \text{ and } j' \text{ are in the same cluster,} \\ d_{jj'} + M, & \text{if the cluster of } j \text{ directly precedes or follows that of } j' \\ 2 \cdot M, & \text{otherwise} \end{cases} \quad (12)$$

Analog to the previous transformation, objective values smaller than $(l + 2) \cdot M$ indicate that the TSP solution represents a feasible GCTSP-GCS solution and the corresponding GCTSP-GCS objective value is obtained by subtracting $(l + 1) \cdot M$. Because of the symmetry of the distance matrix, any TSP tour can be reversed and the resulting tour has identical objective value. In a GCTSP-GCS solution, a reversed tour also results in a reversed cluster sequence. Thus, this case needs to be handled by checking whether the first visited node in the TSP tour belongs to the first or last cluster of the given cluster sequence.

Recall that both the GCTSP-GCS and GCTSP-OCS allow for arbitrary distance matrices defining the distances among picking positions derived from any distance metric. In the following sections, however, we will show that the special distance matrices in parallel-aisle warehouses can be exploited to derive more efficient algorithms.

3 Solving the single-block warehouse CTSP with given cluster sequence

The GCTSP-GCS is well-known to be strongly NP-hard (Potvin and Guertin 1998). However, in the following, we show that this does not hold for the single-block WCTSP-GCS.

Theorem 1 *The single-block WCTSP-GCS is solvable in $\mathcal{O}(m^3 + rm^2)$, where r is the number of aisles in the warehouse and m is the total number of required picking positions.*

Proof of Theorem 1. We present a DP procedure, which is able to solve the single-block WCTSP-GCS in polynomial time. Let $k = 1, \dots, l$ denote the given processing order of the picking orders P_k , and let P_0 and P_{l+1} be two virtual picking orders containing only the depot 0. The DP consists of stages $s = 0, \dots, l + 1$ (with virtual start stage $s = 0$ and end stage $s = l + 1$) representing the picking orders (clusters) P_s . Each stage s contains a number of $|P_s|$ states (s, j') with $j' \in P_s$, which define that picking position j' is the last one visited when completing picking order P_s .

The following Bellman recursion applies:

$$W(s, j') = \min_{j \in P_{s-1}} \left(W(s-1, j) + \Omega((s-1, j), (s, j')) \right). \quad (13)$$

$W(s, j')$ denotes the objective value of state (s, j') , i.e., the total distance which the picker has traveled after picking orders P_0 through P_s with j' as the last item picked for order P_s . Ω is the partial objective value associated with a transition from state $(s-1, j)$ to (s, j') , i.e., the distance required to pick all items in order P_s when starting at picking position j from order P_{s-1} and ending at position j' .

For the initial objective value, we set $W(0, 0) = 0$. Solving the single-block WCTSP-GCS then corresponds to finding a state of final stage $s = l + 1$ with minimum objective value (total walking distance).

To calculate Ω , we determine a shortest order picking path starting at j , visiting all picking positions $P_s \setminus j'$ and ending in position j' using the routing algorithm presented in Section 4, which extends the algorithm of Ratliff and Rosenthal (1983) and has a runtime complexity of $\mathcal{O}(m + r)$. The DP has no more than m^2 transitions, and each transition requires the computation of a partial objective value by means of the routing algorithm. Thus, the runtime complexity is $\mathcal{O}(m^3 + rm^2)$. \square

4 Picking a single order with given start and end point in a single-block parallel-aisle warehouse

This section describes the computation of the partial objective value Ω associated with a transition from stage $s - 1$ to s in the DP method described above. It extends the algorithm of Ratliff and Rosenthal (1983) such that the picking tour does not need to form a closed loop but is a picking path. Input to the algorithm is a designated start point $j \in P_{s-1}$, a designated end point $j' \in P_s$, and a set of vertices P'_s representing the remaining set of picking positions $P_s \setminus j'$ of order s . In the context of the DP, j and j' correspond to the last picking positions of orders $s - 1$ and s , respectively. Like the original algorithm of Ratliff and Rosenthal (1983), our method relies on a single-block parallel-aisle warehouse structure.

The basic property utilized by the algorithm of Ratliff and Rosenthal (1983) is that in optimal solutions aisles can only be passed by the picker in a restricted number of ways, e.g., once through the complete aisle or two loops from the back and front cross aisle. These vertical aisle configurations are to be interconnected horizontally via the cross aisles, for which also only a limited number of possible traversals exists. Given these potential vertical and horizontal configurations, where only some of the former are compatible with the latter, a dynamic programming scheme then connects fitting configurations to states in a step-wise manner until all relevant aisles of the warehouse are visited. In this section, we elaborate on how these basic ingredients have to be adapted in order to integrate a given start and end point.

In Section 4.1, we introduce a representation of the warehouse and of picking paths using undirected multi-graphs. Section 4.2 describes the construction of a minimum-length undirected picking path using this representation. In this way, we provide the means to compute the partial objective value Ω , which we illustrate at an example in Section 4.3. Section 4.4 presents an efficient method for obtaining a directed picking path from its undirected representation. The definitions and theorems in Sections 4.1–4.4 are intentionally kept as close as possible to those of the original paper of Ratliff and Rosenthal (1983). This includes a similar terminology to simplify the discussion for readers that are familiar with the original algorithm. Proofs for all theorems can be found in the online appendix A. Finally, Section 4.5 shows how the S-shape and largest gap heuristic can be modified to handle given start and end points of the picking path.

4.1 Graph representation and preliminaries

In this section, we show how the graph definition of Ratliff and Rosenthal (1983) has to be extended to include a given start and end point. With given j, j', P'_s and r , we define a warehouse graph $G = (V, E)$, whose vertices V represent j and j' , every element in P'_s and the front and rear locations e_i and e'_i in every aisle $i = 1, \dots, r$. Set E consists of an unlimited number of parallel edges between every pair of vertices corresponding to adjacent locations in the warehouse. Associated with every edge is the distance or time it takes to travel between the locations corresponding to the incident vertices, which will be referred to as the length of an edge in the following. Parallel edges always have the same length. Figure 3 shows an example warehouse graph with $r = 5$ and $|P'_s| = 9$. Vertices representing the picking positions in P'_s are denoted by $v_p, p = 1, \dots, |P'_s|$.

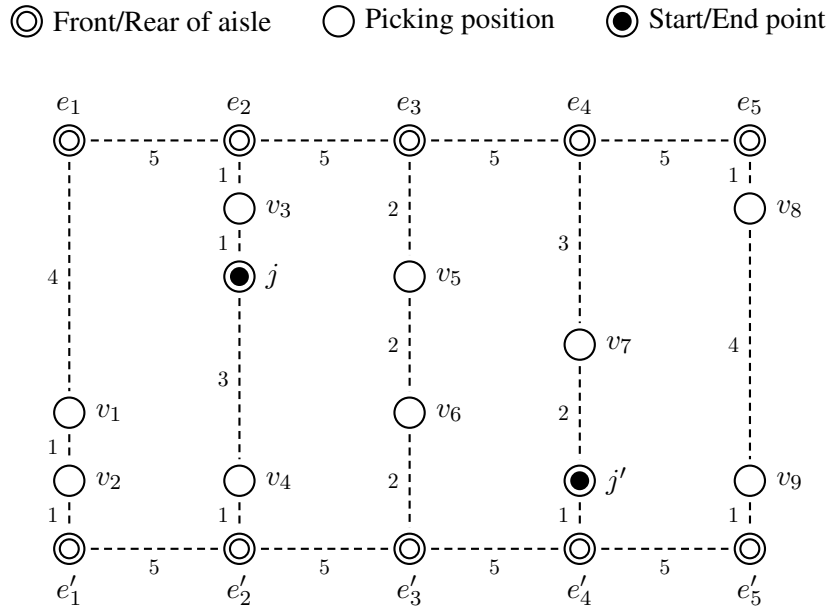

Figure 3: Example warehouse graph with $r = 5$ and $|P'_s| = 9$. Dashed lines represent an unlimited number of parallel edges.

In general, a subgraph of G is a graph whose set of vertices is a subset of those in G , and which has fewer or the same number of edges between any pair of vertices as G has between them. The length of a subgraph is defined as the total length of all its edges.

Definition 1 (Path Subgraph) *A path subgraph (PS) T is a subgraph of G , from which a directed picking path can be constructed such that every arc of the picking path corresponds to exactly one edge in T .*

To differentiate between a picking path and a path subgraph according to Definition 1, recall that a picking

path represents a path starting at position j , visiting all articles $v_p \in P'_s$ and finishing at position j' , hence it is represented by a directed graph.

A PS can be interpreted as an intermediate representation of a picking path where all arcs have been replaced by edges. Note that a PS represents at least two picking paths because there are at least two ways of assigning a direction to an undirected path and because the PS might contain cycles, which can be oriented in two different ways. Because the single-block WCTSPs are symmetric, a PS has the same length as all directed picking paths which can be derived from it. Theorem 2 states the formal properties of a PS. It is the adaption of Theorem 1 from Ratliff and Rosenthal (1983) picking paths with non-identical start and end point.

Theorem 2 (Path Subgraph Properties) *A subgraph $T \subset G$ is a path subgraph if and only if*

1. *vertices P'_s have nonzero even degree in T .*
2. *vertices j and j' have nonzero odd degree in T .*
3. *vertices e_i and e'_i have even or zero degree in T for all $i = 1, \dots, r$.*
4. *excluding vertices with zero degree, T is connected.*

The meaning of Theorem 2 can be easily understood when interpreting the notion of the degree of a vertex as the number of times that the picker passes the picking position represented by the vertex. The number of connected components in a PPS is the number of non-intersecting picking paths, i.e., a connected component represents the picking path of a single picker, and consequently, a valid PS can only contain one connected component.

Similar to the algorithm of Ratliff and Rosenthal (1983), the minimum-length PS is constructed incrementally by iterating over all aisles from 1 to r . To this end, L_i^- denotes a subgraph of G including e_i and e'_i and everything (i.e., edges and vertices) to the left of these vertices, whereas L_i^+ includes L_i^- and everything on aisle i . An illustration of L_3^- and L_3^+ for the example warehouse graph above can be found in Figure 4. Similarly, we define R_i^- as a subgraph of G including e_i and e'_i and everything to the right of these vertices, and R_i^+ as a subgraph of G containing R_i^- and everything on aisle i . In order to keep notation simple, the use of L_i in a statement means that it holds when L_i is substituted by either L_i^- or L_i^+ . The use of L_i and R_i together in a statement means that the statement holds when either $L_i = L_i^-$ and $R_i = R_i^+$ or $L_i = L_i^+$ and $R_i = R_i^-$.

Definition 2 (Partial Path Subgraph) *Using the previous definitions, we define a subgraph $T \subset L_i$ to be an L_i partial PS (L_i PPS) if there exists a subgraph $T^c \subset R_i$ such that $T \cup T^c$ forms a valid PS. The subgraph T^c is called a completion of T .*

Theorem 3 (Partial Path Subgraph Properties, see Theorem 2 of (Ratliff and Rosenthal 1983)) *A subgraph $T \subset L_i$ is an L_i PPS if and only if*

1. *every vertex in $T \setminus \{j, j'\}$ has even or zero degree,*
2. *the degrees of vertices $P'_s \cap L_i$ are nonzero and even in T ,*
3. *vertices $L_i \cap \{j, j'\}$ have odd degrees in T ,*
4. *excluding vertices with zero degree, T is either empty, has a single connected component containing at least one of e_i and e'_i or two connected components of which one contains e_i and the other one contains e'_i .*

Figure 4: Subgraphs L_3^- (a) and L_3^+ (b) of the example warehouse graph. Dashed lines again represent an unlimited number of parallel edges.

Definition 3 (Equivalent Partial Path Subgraphs) *With given $T^1 \subset L_i$ and any $T^c \subset R_i$ such that $T^1 \cup T^c$ forms a valid PS, another $T^2 \subset L_i$ is said to be equivalent to T^1 , if $T^2 \cup T^c$ also forms a valid PS.*

Graphically speaking, if two PS contain two equivalent L_i PPS, then these PPS can be exchanged between the two PS without invalidating either of them.

Theorem 4 (Equivalence Conditions, see Theorem 3 of Ratliff and Rosenthal (1983)) *Two PPSs T^1 and T^2 of L_i are equivalent if*

1. both e_i and e'_i have the same degree parity (even, odd, or zero) in T^1 and T^2 ,
2. excluding vertices with zero degree, both T^1 and T^2 have the same number of connected components.

Every L_i PPS belongs to exactly one equivalence class, which is characterized by the degree parities of e_i and e'_i and the number of connected components. Hence, we denote the equivalence class as a triple (degree of e_i , degree of e'_i , number of connected components), without the braces and commas. For instance, UE1 indicates that the degree of e_i is odd (U for *uneven*, because O for odd could be confused with 0 for zero) and the degree of e'_i is even (E), and there is only one component (1).

Theorem 5 (Possible Equivalence Classes, see Corollary 3.1 of Ratliff and Rosenthal (1983)) *Every possible L_i PPS belongs to one of a set C of 14 equivalence classes*

$$C = \{000, 001, E01, 0E1, EE1, UU1, EE2, UU2, U01, 0U1, UE1, EU1, UE2, EU2\}. \quad (14)$$

4.2 Minimum length path subgraph construction

This section defines the vertical and horizontal configurations in which aisles and cross aisles, respectively, can be traversed in optimal solutions and how these configurations are connected in a dynamic program. We know that there is a finite set of equivalence classes, and that every L_i PPS belongs to exactly one of them. We now show how to construct a minimum-length L_i PPS for each equivalence class, starting at $i = 1$ going through $i = 2, \dots, r$. The shortest L_r^+ PPS from the set of equivalence classes $\{001, E01, 0E1, EE1\}$ will

be the desired minimum-length PS because according to Theorem 2, a valid order picking path graph must be connected and must possess even or zero degree in e_r and e'_r . We begin with the following observation:

Lemma 1 (Maximum Vertex Degrees) *A minimum length PS contains no more than two edges between any pair of vertices.*

Corollary 1 (Possible Edge Configurations) *Following from Lemma 1, there exist 18 possible edge configurations for traversing any aisle, which will be referred to as vertical edge configurations. Further, there exist 9 edge configurations for crossing between adjacent aisles, which will be referred to as horizontal edge configurations.*

The 18 possible vertical edge configurations are shown in Figure 5. Expanding an L_i^- PPS with a vertical edge configurations from Figure 5 will result in an L_i^+ PPS. Configurations 1–5 apply in case aisle i neither includes j nor j' . Configuration 6 applies, if aisle i does not contain any picking positions from $P_k \cup \{j, j'\}$. If aisle i contains either j or j' , configurations 7–12 are used for expansion, changing the mode in the resulting L_i PPS from even to odd or vice versa. Configurations 13–17 are applicable if aisle i contains both j and j' . For configuration 4, 11, 12, 13, 16a, and 16b, the longest distance between any two adjacent vertices from $P'_s \cup \{j, j'\}$ is not traversed. For configuration 2, 3, 7, 8, 14, and 15, the longest distance between e_i or e'_i and its adjacent vertex from $P'_s \cup \{j, j'\}$ is not traversed. Configurations 16a and 16b are differentiated for clarity because both j and j' are either contained in the upper or in the lower component of the configuration, but adding either of them to an L_i^- PPS results in an L_i^+ PPS of the same equivalence class for both 16a and 16b. The one of shorter length will be referred to as configuration 16. Finally, configuration 18 represents the trivial case, where all vertices P'_s, j and j' are located in the same aisle.

Table 2 shows the equivalence classes for L_i^+ that result from adding a vertical edge configuration from Figure 5 to an L_i^- PPS of a given equivalence class. The leftmost column states the equivalence class of the L_i^- PPS. A dash (–) indicates infeasible expansions because in those cases either no valid completion exists, or the resulting PS cannot be optimal. An example expansion of an L_3^- PPS with vertical edge configuration 1 is shown in Figure 6.

Figure 7 shows the 9 possible horizontal edge configurations. Adding one of them to an L_{i-1}^+ PPS will result in an L_i^- PPS. As a special case, configuration 5 only applies if there are no picking positions to the right of aisle $i - 1$.

Table 3 states the equivalence class of an L_i^- PPS resulting from adding a horizontal edge configuration from Figure 7 to an L_{i-1}^+ PPS of a given equivalence class. For instance, an L_i^- PPS of equivalence class 0E1 results from adding edge configuration 3 from Figure 7 to an L_{i-1}^+ PPS of equivalence class 0E1 or EE1.

To find the minimum-length PS, the algorithm starts in aisle 1, with an empty L_1^- PPS belonging to equivalence class 000. For the current aisle i , all L_i^- (L_i^+) PPSs are expanded with all applicable edge configurations from Figure 5 (7), leading to a set of L_i^+ (L_{i+1}^-) PPSs. From this set, we only keep the shortest L_i PPS for each equivalence class. Then, the algorithms continues with the next aisle $i + 1$. As stated above, for the last aisle r , the shortest L_r^+ PPS belonging to the set of equivalence classes $\{001, E01, 0E1, EE1\}$ is the desired minimum-length PS.

To determine the runtime complexity, we first observe that the algorithm iterates over r aisles. Second, in order to expand the L_i PPSs for every aisle i , the algorithm constructs the (fixed number of) edge configurations. Here, the construction of vertical configurations 4, 11, 12, 13 and 16 require the iteration over all picking positions located within aisle i . Thus, the algorithm iterates over no more than $\mathcal{O}(|P_k|)$ picking positions in total. Because $|P_k| \leq m$, this results in a runtime complexity of $\mathcal{O}(m + r)$ for determining the minimum-length PS.

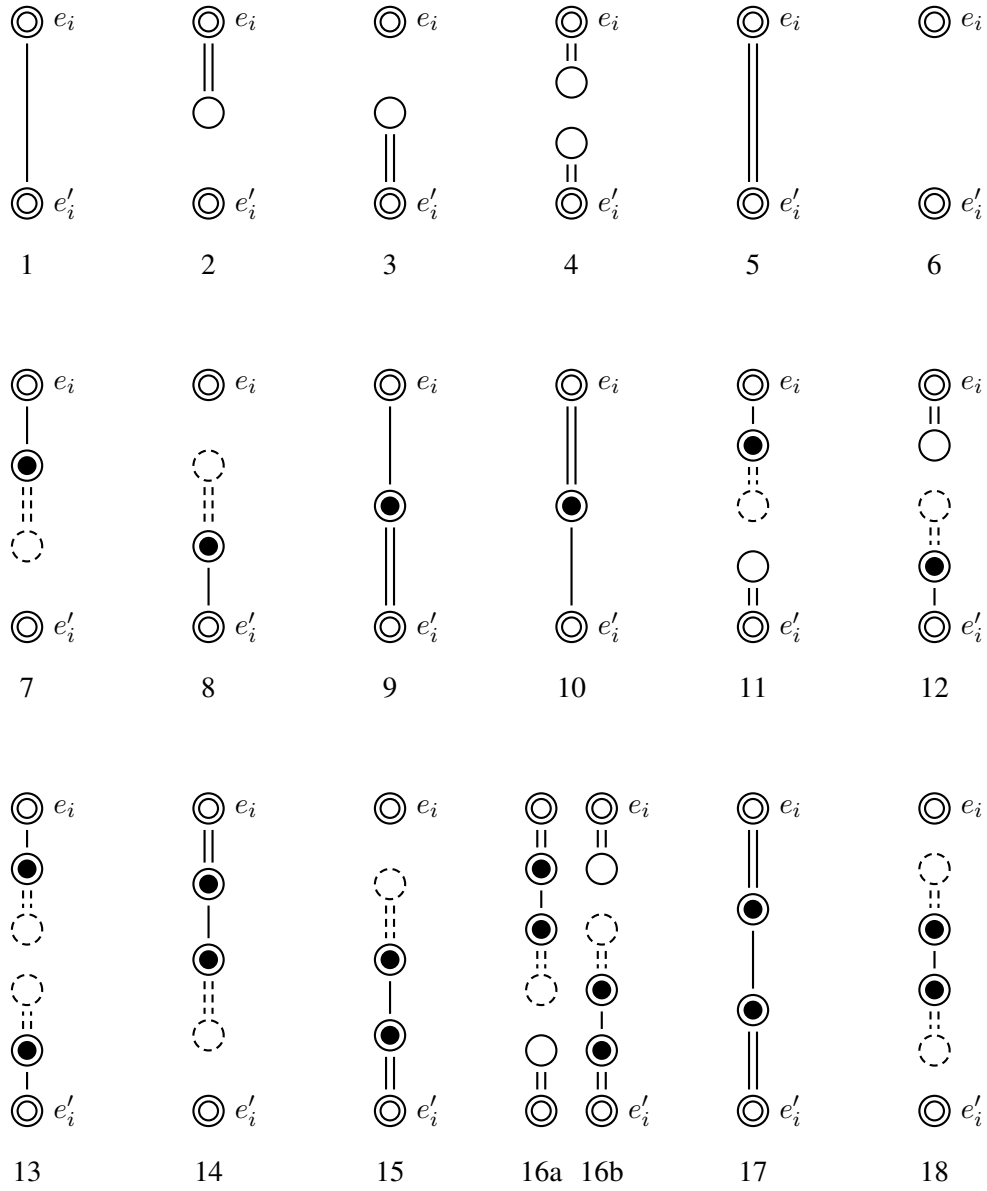

Figure 5: Possible vertical edge configurations for traversing any aisle i . Dashed parts are optional.

4.3 Numerical example

To illustrate the procedure described above, we determine the minimum-length PS for the example given in Figure 3. First, we calculate the shortest L_1^+ PPSs by adding all applicable vertical edge configurations from Figure 5 to the initially empty L_1^- PPS of equivalence class 000. Because aisle 1 contains neither j nor j' , vertical edge configurations 1–5 are used, and all resulting L_1^+ PPSs are of even mode. Vertical edge configuration 6 is not applicable because aisle 1 is not empty. From Table 2, we see that adding vertical edge configuration 1 to a PPS of equivalence class 000 leads to a PPS of equivalence class UU1, whereas adding vertical edge configuration 2 to a PPS of equivalence class 000 leads to a PPS of equivalence class E01. The resulting equivalence classes for edge configurations 3, 4 and 5 are 0E1, EE2 and EE1 respectively. Secondly, we add horizontal edge configurations from Figure 7 to the L_1^+ PPSs to obtain the shortest L_2^- PPSs. From Table 3, we see that for the equivalence classes obtained in the previous step, only horizontal edge configurations 1–5 are applicable. The PPS of equivalence class EE1 can be expanded with more than one horizontal edge configuration. Also, we obtain more than one PPS for equivalence classes E01 and 0E1, in which case we keep the shortest one for each equivalence class. The shortest L_i^+ and L_i^- PPSs for the following aisles can be calculated in the same fashion by using the transition matrices in Tables 2 and 3, respectively. Because j is located in aisle 2, the algorithm transitions into odd mode by constructing the L_2^+ PPSs using vertical edge configurations 7–12. The algorithm transitions back into even mode by constructing the L_4^+ PPSs because vertex j' is located in aisle 4.

Table 4 shows a cost and transition matrix for the example in which each row corresponds to an L_i PPS equivalence class. The entries of the cost matrix are triplets of the form (costs, equivalence class of predecessor, edge configuration). The shortest L_5^+ PPS among equivalence classes 001, E01, 0E1, EE1 is the minimum-length PS, which in the given example is of equivalence class EE1 and has length 57. Tracing back through the matrix using the denoted predecessors, the shortest tour is obtained by the sequence of edge configurations $V_1 = 3, H_2 = 3, V_2 = 8, H_3 = 7, V_3 = 1, H_4 = 6, V_4 = 8, H_5 = 1, V_5 = 1$, where V_i and H_i denote the vertical and horizontal edge configuration in aisle i , respectively. The edge configurations of the minimum-length PS depicted in Figure 8 are given by the underlined entries in the cost matrix.

Table 4: Cost matrix for the example in Figure 3.

4.4 Picking path construction

To obtain the directed order picking path of the order picker from a given PS, a procedure similar to the one presented in Ratliff and Rosenthal (1983) can be used.

Theorem 6 (Picking Path Construction Procedure) *Given a valid PS, a picking path can be constructed by the following procedure:*

1. Start at vertex j .
2. If there is a pair of unused parallel edges incident to the current vertex, use one of them to go to the next vertex, then continue with step 2.
3. If there are any unused single edges (i.e., not one of a pair of parallel edges), use one of them to go to the next vertex, then continue with step 2.
4. If there is a pair of parallel edges with one edge used and one edge still unused, use the unused edge to go to the next vertex, then continue with step 2.
5. Stop. Now the currently visited vertex is j' , and the order picking path is complete.

4.5 Heuristic routing strategies for picking a single order with given start and end point

In practice, warehouse managers often do not use an optimal routing policy because optimal solutions may have a complicated shape and may cause confusion for the pickers (de Koster et al. 2007). To address this issue, we modify the well-known S-shape and largest gap heuristics (see Hall 1993) to replace the optimal routing policy presented above. These routing heuristics are originally designed for a setting in which the picker returns to the depot after each completed order. They are briefly described in the following:

- The S-shape heuristic traverses an aisles either entirely (if picks are required in there) or not at all (if no pick is required). This leads to S-shaped tours where pickers access the front and back cross aisle in an alternating manner.

- The largest gap heuristic divides the warehouse into two areas where the largest distance between two neighboring picking positions within the same aisle partitions picks either into the front and back part. Picks in the front part are accessed from the front cross aisle and picks in the back part are accessed from the back cross aisle.

We adapt both heuristics to our setting in which the picker starts from a given starting position j , collects all items of order P_k , and ends at position j' . The original heuristics are modified such that (i) they remain simple enough to be executed by the pickers with only minimum guidance, and (ii) they yield the same results as the original heuristics if start and end point are located at the depot.

The first step in both modified heuristics is to determine the first picking position v_f to be visited after the starting position as follows:

- Construct a set B of candidate positions for v_f : Let A_l (A_r) denote the leftmost (rightmost) aisle that contains items included in P_k . If A_l (A_r) contains two or more picking positions, the frontmost and rearmost positions in A_l (A_r) are added to B . If A_l (A_r) contains only one picking position, add this position to B . Note that $1 \leq |B| \leq 4$.
- Determine the subset $B' \subseteq B$ of positions that are closer to j than to j' . If B' is not empty, v_f is the position in B' that is closest to j . Otherwise, v_f is the position in B that is closest to j .

With given v_f , the modified heuristics work as follows: first go from j to v_f on the shortest path and pick all items that are passed on the way. If all items in P_k have been picked, go directly to j' . If no additional items have to be picked in the aisle containing v_f , continue traversing the aisle and stop at the entry. If additional items have to be picked in the aisle, traverse the aisle in the direction of these items and continue until the last item is picked. In case P_k is completed, go directly to j' . Otherwise continue to the entry of the aisle. The picker is now located at the entry of an aisle which is either to the left or right of all remaining aisles that contain items to be picked. We interpret this position as the position of the depot in the original S-shape or largest gap heuristic, and all remaining items are now picked in the same way as in the original heuristic. In contrast to the original heuristics, the picker directly goes to j' after the last item is picked.

5 Solving the single-block warehouse CTSP with open cluster sequence

In this section, we first show that the single-block as well as multi-block WCTSP-OCS are NP-hard in the strong sense. Note that such a proof is required due to the special distance matrices occurring in parallel-aisle warehouses. Furthermore, we determine a lower bound on the objective value of the single-block WCTSP-OCS (Section 5.1). In Section 5.2, we present a greedy heuristic for the single-block WCTSP-OCS, which aims at short runtimes while keeping a decent solution quality. As the numerical experiments will show, the other end of the spectrum, i.e., a heuristic with very good solution quality but longer runtimes is already available by using the transformation described in Section 2.3 together with a state-of-the-art heuristic TSP solver.

5.1 Complexity and lower bound

Theorem 7 *The single-block as well as multi-block WCTSP-OCS are NP-hard in the strong sense.*

We prove this theorem by a reduction from the Hamiltonian Path problem (HPP), which is well-known to be strongly NP-hard (Garey and Johnson 1979). It can be stated as follows: Given an undirected graph

$G = (V, E)$, the HPP determines whether or not a path through the graph exists that visits all vertices $v \in V$ exactly once.

Proof of Theorem 7. Consider an instance I of HPP given by graph $G = (V, E)$. We construct an instance I' of the WCTSP-OCS in polynomial time as follows. We introduce $l = |V|$ picking orders and $r = |E|$ aisles according to the layout depicted in Figure 2a. We, thus, have a picking order for each node. Furthermore, we have a distinct aisle for each edge in G . Each aisle corresponding to an edge (v, v') contains one picking location for the picking order corresponding to v and one picking location for the picking order corresponding to v' , both of which are located in the middle of the aisle. Thus, in total we have $m = 2r$ picking positions. Note that if and only if there is an edge connecting nodes v and v' , the orders corresponding to these nodes have an aisle to be visited in common. The distance from the entry of an aisle to its middle is λ (see Figure 9b). The distance between the leftmost and the rightmost aisle is $\beta < \frac{\lambda}{2l}$. The start position of the picker is at the beginning of a facultative rack (indicated by position 0 in Figure 9b).

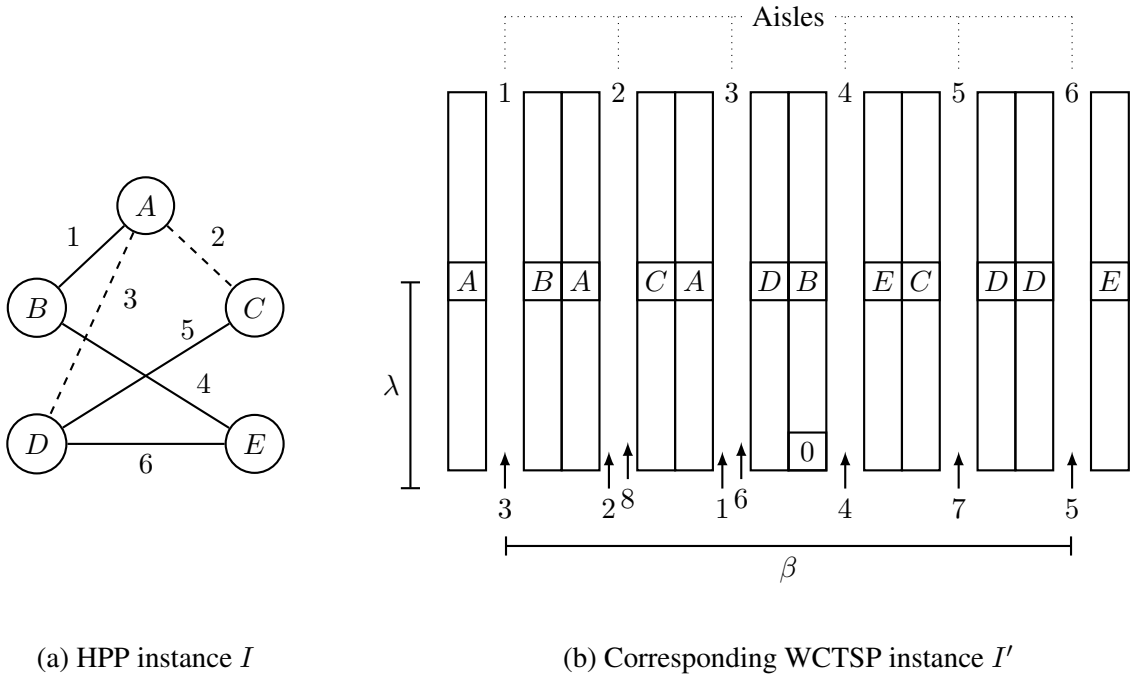

Figure 9: Transformation of an HPP instance (a) into a WCTSP instance (b).

We will now show that I is a yes-instance if and only if there is a feasible solution to I' with a total travel distance of less than $2\lambda \cdot (m - l + 1)$.

Existence of a Hamiltonian path with vertices v_0, v_1, \dots, v_l in I implies a solution to I' with less than $2\lambda \cdot (m - l + 1)$ total travel distance, which can be constructed in the following way: We start at position 0 and pick every item in v_0 such that we end in the middle of the aisle corresponding to edge (v_0, v_1) . For every v_k with $0 < k < l$, we start in the middle of the aisle corresponding to edge (v_{k-1}, v_k) and pick all items of the order corresponding to vertex v_k such that we end in the middle of the aisle corresponding to (v_k, v_{k+1}) . Finally, we start in the middle of the aisle corresponding to (v_k, v_{k+1}) , pick all items of the order corresponding to vertex v_l and return to position 0.

Visiting an aisle and walking from the entry of an aisle to the picking position located in the middle and back takes a distance of 2λ . In the worst case, any picking position is visited individually, so that we have m aisle visits. The Hamiltonian path, however, allows us to save $l - 1$ aisle visits because the first item of a successive order can directly be picked without additional walking. For any order, the horizontal travel in

front of the aisles can always be executed within a walking distance of at most twice the warehouse width $\beta < \frac{\lambda}{2l}$. Thus, the total horizontal travel cannot exceed λ , and the total distance of our constructed solution to I' does not exceed $2\lambda \cdot (m - l + 1)$.

If there is a solution S to I' with total walking distance of less than $2\lambda \cdot (m - l + 1)$, the first picking position visited for each picking order (except for the very first order) must be in the same aisle as the last position of the preceding order. Hence, each order must have at least one aisle in common with its preceding order in S , and, thus, there must be an edge between the nodes corresponding to these picking orders. Hence, the sequence of nodes (picking orders) corresponding to S represents a Hamiltonian path. In Figure 9b, the numbers at the bottom indicate the aisle visiting sequence of a solution that fulfills this requirement: first, the picker visits aisle 3, collecting the first item of order A . Then, the picker moves to aisle 2 and collects the second item of order A . Next, to aisle 1, collecting the last item of order A and the first item of order B , before moving to aisle 4 to collect the second item of order B and the first item of order E . The picker proceeds accordingly and visits aisles 6, 3, 5, and 2. The order processing sequence is (A, B, E, D, C) , which directly corresponds to the sequence of nodes in the Hamiltonian path in Figure 9a. \square

Strictly speaking, this proof is only for the single-block parallel-aisle warehouse layout depicted in Figure 2a. However, if we imagine the aisles defined above only as the first block up to the middle aisle (with no additional picking positions beyond), then the same transformation also holds for the multi-block WCTSP-OCS (Figure 2b).

Lemma 2 (Lower Bound) *A lower bound for the single-block WCTSP-OCS is given by*

$$\text{LB} = \sum_{k=1}^l \left(\text{SP}(P_k) + \min_{j \in P_k, j' \in P \setminus P_k} d_{jj'} \right) + \min_{j \in P \setminus 0} d_{0j}, \quad (15)$$

where $\text{SP}(P_k)$ is the length of the shortest Hamiltonian path through all positions in P_k .

Proof of Lemma 2. Because all positions in a cluster must be visited successively, each cluster will at least require the length of the shortest Hamiltonian path through all its positions, which is expressed by the first term within the sum in (15). The second term within the sum originates from the fact that every cluster must be left exactly once. The last term accounts for having to leave the depot position. \square

Note that for the single-block WCTSP-OCS, the value of $\text{SP}(P_k)$ can be computed efficiently by means of the routing algorithm from Section 4, where start and end points j and j' are chosen from P_k such that $\text{SP}(P_k)$ is minimum.

5.2 Greedy best insertion heuristic

In this section, we present a greedy algorithm, called best insertion (BI), for the single-block WCTSP-OCS. The method starts from an order sequence only containing the two instances of the depot P_0, P_{l+1} . Then, all possible combinations of remaining orders and potential insertion positions are evaluated by means of the described DP, and the best combination is chosen. This process is repeated until all orders have been inserted. There are no more than l^2 combinations of orders and insertion positions, and the procedure performs l insertions in total. Thus, the runtime complexity of BI is $\mathcal{O}(l^3 \cdot (m^3 + rm^2))$.

6 Computational experiments

This section describes the numerical studies to assess the performance of the proposed algorithms and to evaluate the benefits of using AGVs to assist order pickers. Section 6.1 introduces the benchmark instances, Section 6.2 provides the parameter settings of the algorithms, and Section 6.3 discusses the results and gives some managerial insights. Finally, in Section 6.4, we study the number of AGVs that is required to support a given number of pickers without causing waiting times.

6.1 Test instances

The instances used in our experiments are based on the instances of Henn and Wäscher (2012). Although the authors introduced these instances for the order batching problem with picker capacity, they can be interpreted as single-block WCTSP instances without requiring any modification (see Section 6.3 for details). We distinguish three benchmark sets, each containing 400 instances:

Original: These are the original instances of Henn and Wäscher (2012) without any modifications. The instances assume a parallel-aisle single-block warehouse as depicted in Figure 2a. The warehouse contains $r = 10$ picking aisles, each with 45 picking positions on both sides. The length of a picking position is 1 length unit (LU). Whenever the picker is leaving an aisle at the top or bottom, she must move 1 LU in vertical direction to reach the cross aisle. The distance between neighboring aisles is 5 LU. The depot is located below the leftmost picking aisle, more precisely 0.5 LU below vertex e'_1 in Figure 3.

The instance set (as well as the other two sets described below) can be further subdivided into two groups, each containing 40 instances for different numbers of picking orders $l \in \{20, 40, 60, 80, 100\}$, resulting in a total of 200 instances per group. In the first group, the frequency for any SKU to appear in an order is uniformly distributed over all SKUs within the warehouse, and, thus, this group is called uniformly distributed demands (UDD). In the second group, called class-based demands (CBD), 10% of the SKUs, all of which are located in aisle 1, make up 52% of the required picking positions; the next 30% SKUs, located in aisles 2-4, make up 36%, and the last 60% of SKUs, located in the remaining six aisles, make up 12% of picking positions. In both groups, the number of picking positions to be visited in each order is uniformly distributed in the interval $[5, 25]$.

Central Depot: This instance set differs from the original one with regard to the location of the depot in the warehouse and the arrangement of the picking aisles: in each instance, the position of the depot is moved from the bottom left to the bottom of the 5th picking aisle, more precisely 0.5 LU below vertex e'_5 in Figure 3. In addition, the picking aisles are rearranged according to the following mapping:

Aisle in original instance:	1	2	3	4	5	6	7	8	9	10
Aisle in modified instance:	5	6	4	7	3	8	2	9	1	10

This mapping also ensures that the article distribution in the modified instances is reasonable for CBD.

Large Orders: This instance set differs from the original one with regards to the number of picking positions per order, which is on average doubled in these instances. To generate a new instance of set Large Orders, we use a pair of instances from set Original: For every set of 40 instances with a given demand distribution type and number of orders l , we combine instances number 1 and 2 from set Original to generate instance 1 of set Large Orders, instances 2 and 3 of set Original to generate instance 2 of

set Large Orders, and so on. Instance number 40 of set Large Orders is generated from instances 40 and 1 of set Original. The instance of set Large Orders is obtained by merging the picking positions of the individual orders in the two instances from set Original, i.e., the two orders with number k in the instances from set Original form order number k of the newly generated instance. In the resulting instances, the number of picking positions per order lies in the interval $[10, 50]$.

The described instance sets are provided as online supplement.

6.2 Solution methods and computational environment

All dedicated WCTSP solution methods presented in this paper are coded in C++. Besides their performance, our numerical studies investigate how well WCTSP instances can be solved by state-of-the-art TSP methods from the literature.

The first such method that we include in our studies is the exact TSP solver Concorde (CC). It is only able to solve symmetric TSP instances, and WCTSP instances first need to be transformed using the rules from Section 2.3. For CC, source code and precompiled binaries are available at <http://www.math.uwaterloo.ca/tsp/concorde.html>. In all our experiments, the precompiled binary of CC is used with default settings and a time limit of 2 hours per run. If the time limit is reached before an optimal solution is found, CC returns an upper bound.

The second method is the Lin-Kernighan-Helsgaun heuristic for the GCTSP presented in Helsgaun (2014) and called CLKH. CLKH itself is based on the transformation of GCTSP instances into TSP instances according to Section 2.3, which are solved using the original LKH heuristic for the TSP with a special parameter setting to account for the particular structure of GCTSP instances. Thus, both methods investigated in our studies actually rely on a transformation of WCTSP instances into TSP instances. The source code of CLKH is available at <http://akira.ruc.dk/~keld/research/CLKH/>. We compiled the source code using GCC 9.1 with full optimizations enabled (-O3).

All experiments were conducted on a computing cluster featuring Intel Xeon E5-2430v2 CPUs with a maximum clock speed of 3.0 GHz and 64 Gb RAM per computing node. On each CPU, only one core was used in order to report meaningful runtimes.

6.3 Impact of AGV assistance on picker routing efficiency

This section describes the experiments to assess (i) the performance of the algorithms proposed in this paper, and (ii) the benefits of using AGVs to assist order pickers. In these experiments, we interpret the benchmark instances from Section 6.1 in different ways:

- Traditional picker routing problem without AGV support: Each order has to be picked independently, and the picker returns to the depot after each completed order. In this case, the sequence in which the orders are processed is irrelevant. We use the solution cost obtained with this variant to assess the potential performance gains obtained through AGV usage.
- Single-block WCTSP-GCS: The order picker is assisted by an AGV, and the picker directly continues picking the next order after each completed one without returning to the depot. The orders are picked in the exact order in which they appear in the instance description. This variant is used to evaluate (i) the performance of our DP algorithm, CC, and CLKH, and (ii) the potential performance gains of freely choosing the order picking sequence in the problem with open order sequence.

- **Single-block WCTSP-OCS:** The order picker is again assisted by an AGV, but the processing sequence of the orders is now part of the decision and not fixed. This variant is used to study the performance of the algorithms CC, CLKH, and BI.

Performance of the solution methods Table 5 provides an aggregate view of the computational results on the benchmark sets from Section 6.1. The instances in each set are grouped according to their demand distribution, i.e., uniformly distributed demands (UDD) vs. class based demands (CBD), and the number of orders $l \in \{20, 40, 60, 80, 100\}$. For each of the solution methods, column $\bar{\Delta}(\%)$ shows the average percentage improvement in travel distance of the results obtained on the considered problem variant (single-block WCTSP-GCS or single-block WCTSP-OCS) compared to the results of the traditional picker routing problem. Note that for CC on the WCTSP-GCS, $\bar{\Delta}(\%)$ is not reported because CC finds the same optimal solutions as DP on all instances. Column \bar{t} reports average runtimes in seconds. For the single-block WCTSP-OCS, column #opt reports the number of instances solved to optimality by CC. Finally, column LB reports the lower bound described in Section 5.1 (also as average percentage improvement with regards to the results of the traditional picker routing problem). The detailed results on each instance are reported in the online appendix B, and the corresponding solutions are provided as online supplement.

Concerning the WCTSP-GCS, our DP is able to solve all individual instances of the three benchmark sets to optimality within fractions of a second. The runtime of DP is neither affected by the demand distribution (UDD and CBD) nor the location of the depot. A slight increase of the runtime can be noted for a larger number of orders, and a notable increase for a larger number of picking positions per order (shown by the results on set Large Orders). However, even on the largest instances with $l = 100$ orders in set Large Orders, the average runtime of DP is below 150 milliseconds, which qualifies the algorithm for real-time applications. CC is also able to find optimal solutions for all WCTSP-GCS instances, however, the runtimes are roughly two orders of magnitude higher than those of DP. The influence of the different problem characteristics on the behavior of CC is very similar to that of DP. CLKH nearly matches the solution quality of DP and CC: it is able to find optimal solutions for 1048 of the 1200 instances (see Tables 8–37 in the online appendix), and the deviations on the remaining instances are very small. However, although the algorithm is heuristic, the average runtimes lie clearly above those of CC for all instance sets. Summarizing, our dedicated DP method significantly outperforms the two comparison methods.

On the WCTSP-OCS instances, CC is able to find and prove the optimal solution for 1175 out of the 1200 instances within the time limit. The objective values of CC on the remaining 25 instances lie on average 0.0007% below those of CLKH and 0.34% above the LB (see Tables 8–37 in the online appendix), indicating a very good solution quality also on these instances. The runtimes tend to increase with a larger number of orders and strongly increase with a larger number of picking positions per order. CLKH is able to match 872 of the 1175 optimal solutions and achieves roughly the same overall average quality within clearly shorter runtimes. The influence of a larger number of orders and a larger number of picking positions are visible but less pronounced than for CC. BI is able to find solutions that deviate by no more than 1.6% from those of CLKH on any of the considered instance groups (combination of instance set and demand distribution) but are found within runtimes that are nearly two orders of magnitude shorter. Finally, we note that the proposed (relatively straightforward) LB is of good quality, on average it does not deviate by more than 1% from the best solution found by CC for any of the considered instance groups. Summarizing, if enough computing time is available, WCTSP-OCS instances of the considered size can be solved to (near-)optimality using CC. If less time is available or even larger instances with regards to the number of orders or the number of picking positions per order are considered, high-quality solutions within runtimes still adequate for a short-

term planning horizon can be obtained by CLKH, and fast solutions for real-time scenarios with decent quality by BI.

Observations on the benefits of using AGVs and the influence of problem parameters Based on the optimal solutions found by DP and CC, we make two general observations that are valid independent of the problem type considered (single-block WCTSP-GCS or WCTSP-OCS) and the type of instances (Original, Central Depot, Large Orders): First, the reduction in travel distance is slightly stronger for larger instances, i.e., instances with a higher number of orders. Second, the reduction in travel distance is higher on the CBD instances compared to the UDD case. In general, the total traveled distance to collect all orders on CBD instances is notably smaller than on UDD instances (see Tables 8–37 in the online appendix). However, the savings achievable through AGV support on the few unfavorable picking orders containing picking positions far from the depot have a larger impact.

Considering the results on the WCTSP-GCS, we note that the reported gains compared to the traditional approach without AGV support are obtained solely by the utilization of AGVs without any further managerial effort (the order processing sequence is given by the instance description and not modified). These gains lie between roughly 14.5% and 18% for instance sets Original and Central Depot and between approximately 12% and 14% for instance set Large Orders. The decrease in gains for set Large Orders stem from the fact that orders with more picking positions require longer travel times, which reduces the relevance of the depot returns and therefore the savings potential of AGV support. For instance set Central Depot, the gains are a slightly smaller than for set Original (with the left-side depot) for demand distribution UDD and slightly larger for CBD.

The results for the WCTSP-OCS show that a (near-)optimal decision on the order processing sequence is able to further increase the gains compared to the traditional approach without AGV support. For the instances of sets Original and Central Depot, the increase of the gains lies between roughly 3.6% and 5.9%; it is slightly higher for demand distribution CBD, and the depot location does not have a major influence. On the instances of set Large Orders, the additional gains are smaller with roughly 2% for UDD and 2.5% for CBD.

Performance of the picker routing heuristics Table 6 reports the results obtained when using the modified S-shape and largest gap heuristics presented in Section 4.5 to route the pickers, i.e., we compute the partial objective values within our DP using these heuristics. We only discuss the results for instance set Original because the main findings do not change when the location of the depot is modified or the number of picking positions are increased (the respective results can be found in Table 38 in the online appendix B). As before, solution quality is measured as relative gap to the optimal solution of the traditional picker routing problem. Columns WCTSP-GCS show the performance of the DP using the modified S-shape and largest gap heuristic to solve the single-block WCTSP-GCS. As comparison values, column Exact→WCTSP-GCS reports the results of the DP when determining the partial objective in optimal fashion, i.e., we repeat the values reported in column DP in Table 5. As additional comparison values, we report the results of the S-shape and largest gap heuristic for the traditional picker routing problem, i.e., in a scenario without AGV support, in columns Traditional. All runtimes are below 100 milliseconds and are therefore not reported.

Table 6 shows that AGV-assisted order picking with heuristic routing strategies is clearly beneficial compared to traditional order picking based on the same heuristics. For both heuristics, utilizing AGVs yields a substantial improvement in route length compared to traditional picker routing by means of the respective heuristic: for S-shape, the average improvement is ~24% on UDD instances (~35% on CBD), for largest gap ~8% on UDD (~20% on CBD). While both heuristics forgo potential cost savings compared to op-

tinally solving the WCTSP-GCS, the S-shape heuristics turns out to be clearly inferior to the largest gap approach. This can be explained by the fact that the number of picking positions per order is relatively small compared to the number of picking aisles, and a traversal strategy is inappropriate if the number of picks per aisle is small (see Hall 1993). However, the most important insight of this study is that routing AGV-assisted pickers heuristically can barely reach the performance of optimally routing pickers without AGV support. Only the largest gap heuristic can improve on the latter scenario by a marginal 1.26% in the CBD instances. Thus, the price of more intuitive heuristic picker tours is huge, and optimal solutions obtained by DP seem a clearly superior choice.

Table 6: Comparison of results on set Original when applying the modified S-shape and largest gap heuristics.

Summary of managerial insights From the practitioner’s perspective, the computational results of this section translate into three main findings:

- Assisting human order pickers with AGVs promises a reduction of picker travel of about 20%. Given the large fraction of unproductive picker travel of around 50% of the pickers’ working hours (Tompkins et al. 2003, de Koster et al. 2007), this indicates considerable potential savings. Naturally, it depends on the labor costs in the respective region whether these potential savings in personnel costs can outweigh the additional investment costs into AGVs.
- Compared to a picker routing based on given order sequences, integrating sequence planning into the optimization task only leads to an additional reduction of picker travel of 2–6%. When deciding the processing sequence of orders, typically, an efficient order picking is only one important aspect. Moreover, the due dates of the orders promised to customers need to be considered, see Sharp et al. (1991) for more details. Our results suggest that by applying our efficient solution procedure for given order sequences, considerable reductions of picker travel can be realized for any order sequence. Thus, selecting order sequences just by their urgency and handing them over to picker routing based on given order sequences seems a simple, yet effective planning approach that leads to a good compromise in the tradeoff between urgency and efficiency.
- Finally, routing the AGV-picker-tandems heuristically with the S-shape or largest gap heuristic seems not a good idea. Compared to optimal solutions considerable performance gains are missed, so that an

investment into AGV-assisted picking should be accompanied by the additional invest into a pick-by-voice or handheld scanner solution, which allows to route the pickers (and their accompanying AGVs) according to optimal solutions.

These three findings base on the assumption that the AGV fleet is properly dimensioned and pickers never have to wait for late AGVs. In the following section, we explore the fleet sizes required to fulfill this assumption.

6.4 Experiments on the AGV fleet size

To investigate the AGV fleet size that is necessary to realize an order picking system without picker waiting, we set up the following experiment. We assume that different numbers of pickers are simultaneously picking orders in the warehouse. The demand type is either UDD or CBD, and we assign to each picker an exclusive instance from the respective Original instance set with $l = 100$. For example, in the case of UDD, picker 1 is assigned instance 100-UDD-1, picker 2 is assigned instance 100-UDD-2, and so on. The instances are treated as instances of the single-block WCTSP-GCS and are solved using our DP.

We determine the AGV fleet size required to realize the solution returned by the DP for a single instance, i.e., a single picker, using the following procedure: Let i_k and j_k denote the first and last item which the picker collects for order P_k . Let t_k (t'_k) be the moment in time in which the picker visits i_k (j_k) on an optimal picking tour determined according to Section 4.4. Assuming that no picker waiting must occur, the AGV that accompanies the picker during the picking of order P_k must start its trip at the depot at time $t_k - \frac{d_{0i_k}}{\sigma}$ such that it arrives simultaneously with the picker at position i_k , where σ is the factor by which the AGV can travel faster than the picker. The AGV will return to the depot at time $t'_k + \frac{d_{j_k0}}{\sigma}$. Using this information, we can determine a set of time intervals for the required AGV trips:

$$S = \left\{ \left[t_0 - \frac{1}{\sigma}d_{0i_0}, t'_0 + \frac{1}{\sigma}d_{j_00} \right], \left[t_1 - \frac{1}{\sigma}d_{0i_1}, t'_1 + \frac{1}{\sigma}d_{j_10} \right], \dots, \left[t_l - \frac{1}{\sigma}d_{0i_l}, t'_l + \frac{1}{\sigma}d_{j_l0} \right] \right\} \quad (16)$$

The number of required AGVs is then given by the maximum number of overlapping intervals over all points in time. Determining the minimum AGV fleet for the given picking tours equals determining the chromatic number in an interval graph (Golumbic 2004) and can be determined in polynomial time. The described approach can also be applied to determine the number of required AGVs if multiple pickers share a common AGV fleet. In this case, all pickers start their picking tours at the depot at the same time. The set S now contains time intervals for the trips of all pickers, and the required number of AGVs can be determined as before.

In the experiments, we vary the speed of the AGVs using σ values from 1 to 4 in steps of 0.5. For all combinations of the number of pickers (1, 5, 10, 20, 40) and σ , we conduct five runs of the described experiment and in each run, the order sequences of the original instances are randomly shuffled. The results are presented in Table 7. The reported values represent the average number of AGVs over five runs divided by the number of pickers.

As a main finding, we witness a pooling effect when the number of pickers increases, i.e., the number of AGVs scales less than linear with an increasing number of pickers. The effect somewhat saturates for a larger number of pickers: when doubling the number of pickers from 5 to 10, the required number of AGVs per picker drops by $\sim 10\%$ (for $\sigma = 1$), from 10 to 20 pickers by $\sim 7\%$, and from 20 to 40 by $\sim 5\%$. As can

be expected, higher AGV speeds lead to a stronger reduction in fleet size. The AGV fleet needs to be slightly larger in case of CBD compared to UDD because the picker routes tend to be shorter for CBD, which in turn leads to more tightly packed time intervals for the AGV trips. Note that in our experiments we do not consider the actual time to pick individual items from their storage locations. Thus, in practice, the required number of AGVs are likely to be even lower than in our experiments and the difference between CBD and UDD even less pronounced.

In case AGVs are not shared between multiple pickers, two AGVs per picker seem to be a reasonable choice: although this number is not sufficient to reliably avoid waiting times in the experiments with $\sigma = 1$ (here more than two AGVs are needed on average), this rule of thumb should work well in practical settings with additional picking times. However, considerable reductions of the AGV fleet are possible, if AGVs are not fixedly assigned to their designated pickers but shared among the picking workforce. Since large e-commerce retailers employ hundreds of pickers per work shift (Boysen et al. 2019), even in a single picking zone, where an AGV sharing can easily be organized, a workforce of 40 pickers is quickly reached. Safety reasons restrict the maximum AGV speeds to walking speed (or allow only a slightly faster velocity), so that lower σ -values of 1.0 or 1.5 are the norm in real-world warehouses. Thus, AGV-per-picker ratios of about 1.5 seem a realistic rule of thumb to roughly approximate the investment costs for establishing an AGV-assisted order picking.

Table 7: Average required number of AGVs per picker for different numbers of pickers and AGV speeds on instance set Original.

# pickers	AGV speed σ						
	1.0	1.5	2.0	2.5	3.0	3.5	4.0
UDD							
1	2.00	2.00	2.00	2.00	2.00	2.00	2.00
5	1.92	1.84	1.72	1.64	1.60	1.56	1.56
10	1.76	1.62	1.54	1.48	1.40	1.36	1.36
20	1.63	1.48	1.42	1.35	1.32	1.29	1.28
40	1.54	1.37	1.30	1.26	1.23	1.21	1.19
CBD							
1	2.00	2.00	2.00	2.00	2.00	2.00	2.00
5	2.00	1.84	1.72	1.68	1.64	1.60	1.60
10	1.82	1.68	1.58	1.52	1.46	1.44	1.42
20	1.69	1.52	1.45	1.39	1.35	1.32	1.29
40	1.62	1.46	1.36	1.31	1.26	1.23	1.21

Summarizing, our results indicate that AGV-assisted order picking promises strong improvements in the order fulfilment process. Thus, it can be projected that this technology will gain importance in the next years, at least as a transitory technology, until finally a fully-automated order picking without human pickers becomes possible.

7 Conclusion

This paper considers AGV-assisted order picking, in which an AGV accompanies a human picker while collecting items from storage positions. Once an order is completed, the AGV returns the collected items to the depot, and the picker can directly meet with another AGV to start collecting the subsequent order. The resulting picker-routing problem is shown to be equivalent to the well-known clustered traveling salesman

problem (CTSP). We show that, contrary to the general CTSP, in single-block parallel-aisle warehouses, the resulting warehouse CTSP (WCTSP) with given cluster sequence is efficiently solvable in polynomial time. To do so, we extend the famous Ratliff and Rosenthal (1983) algorithm for order picking in single-block parallel-aisle warehouses and repeatedly solve it as part of a dynamic programming procedure. The developed procedure outperforms the high-quality TSP solvers Concorde and Lin-Kernighan-Helsgaun used together with a transformation of the instances. To also solve the WCTSP with open cluster sequence, we integrate our DP procedure into a greedy insertion heuristic and achieve decent solution quality in very short runtimes. Better-quality solutions within longer runtimes are obtained for this problem variant by using an instance transformation plus Concorde or Lin-Kernighan-Helsgaun.

From the practitioner's perspective, our main findings are the following:

- Compared to a traditional warehouse setting in which the picker has to return to the depot each time a pick list is completed, AGV-assisted order picking reduces the travel distance by about 20%, which indicates a potential of substantial cost savings in real-world warehouses.
- The additional gains that can be achieved by deciding the order sequence are only moderate. Therefore, a simple practical planning approach could determine order sequences by urgency, apply our solution procedure for the single-block WCTSP-GCS, and still gain considerably shorter travel distances compared to a traditional setting without AGVs.
- When opting for AGV-assisted order picking, the AGV-picker-tandems should not be routed using heuristic methods, i.e., S-shape or largest gap heuristic. When applying a heuristic routing, AGV-assisted picking barely leads to the same performance as optimal routing policies without AGV assistance.
- AGVs should not fixedly be assigned to designated pickers but shared among the picker workforce. The latter enables a pooling effect, so that in larger warehouses only about 1.5 AGVs per picker are required to avoid excessive idle time of pickers waiting for delayed AGVs.

AGV-assisted order picking leaves plenty of room for future research. Our basic picker-routing problem could, for instance, be extended by further characteristics of practical relevance. AGVs not being able to pass each other in narrow aisles have already been considered in other warehouse settings (Hong et al. 2012). Extending our problem by non-passing constraints requires the solution of a holistic problem in which all picker paths need to be coordinated. Furthermore, the following alternative routing policy could be evaluated. Instead of following a picker while completing an order, AGVs could stop at the relevant storage positions and wait there until some picker, that may vary from item to item, has placed the respective SKU onto the AGV. Again, a holistic problem coordinating all AGVs and pickers is to be solved. Such a flexible policy promises more efficient picker paths compared to our order-by-order policy. Its major drawback, however, is that once a delay occurs at some storage positions, this may induce further delays of all other AGVs and pickers, so that a complex online control system is required. A comparison of both policies with regard to the resulting picker travel times could illustrate the benefit of such a complex online control system.

Picker routing in AGV-assisted order picking systems

Online appendix

A Proof of theorems

In this section we provide the proofs for the theorems from Sections 4.1–4.4. We repeat all theorems prior to their respective proofs.

A.1 Theorems of Section 4.1

Theorem 3 (Partial Path Subgraph Properties) A subgraph $T \subset L_i$ is an L_i PPS if and only if

1. every vertex in $T \setminus \{j, j'\}$ has even or zero degree,
2. the degrees of vertices $P'_s \cap L_i$ are nonzero and even in T ,
3. vertices $L_i \cap \{j, j'\}$ have odd degrees in T ,
4. excluding vertices with zero degree, T is either empty, has a single connected component containing at least one of e_i and e'_i or two connected components of which one contains e_i and the other one contains e'_i .

To make the proof of Theorem 3 more comprehensible, we first introduce the notion of PPS modes. This feature of a PPS has no equivalent in Ratliff and Rosenthal (1983), because it is a direct consequence from the extension to picking paths with non-identical start and end points. Let $A(v)$ be the aisle in which vertex $v \in V$ is located.

Lemma 3 (Partial Path Subgraph Modes) *For any subgraph $T \subset X_i$ with $X_i \in \{L_i^+, L_{i+1}^-\}$ that fulfills the conditions given in Theorem 3, we can distinguish two different modes depending on aisle i :*

1. *If $i < \min(A(j), A(j'))$ or $i \geq \max(A(j), A(j'))$, the sum of the degrees of e_i and e'_i is even in T , and all X_i PPSs are said to be of even mode.*
2. *If $i \geq \min(A(j), A(j'))$ and $i < \max(A(j), A(j'))$, the sum of the degrees of e_i and e'_i is odd in T , and all X_i PPSs are said to be of odd mode.*

Proof of Lemma 3. The statement follows directly from the fact that, for any undirected graph, the sum of the degrees of all vertices is even, or equivalently, the number of vertices with odd degree must be even. Consider case 1. of Lemma 3: Either none or both of vertices j and j' are contained in the L_i PPS, both j and j' have odd degree, and all other vertices except for e_i and e'_i have even or zero degree. Thus, the sum of the degrees of vertices e_i and e'_i must be even. Now consider case 2. of Lemma 3: Exactly one of vertices j and j' is contained in the L_i PPS, thus the sum of the degrees of vertices e_i and e'_i must be odd. \square

Note that according to Lemma 3, if $A(j) = A(j')$, every L_i PPS is of even mode for all aisles $i = 1, \dots, r$, and, in any case, every L_r^+ PPS is of even mode. An illustration of L_i PPS modes is given in Figure 10.

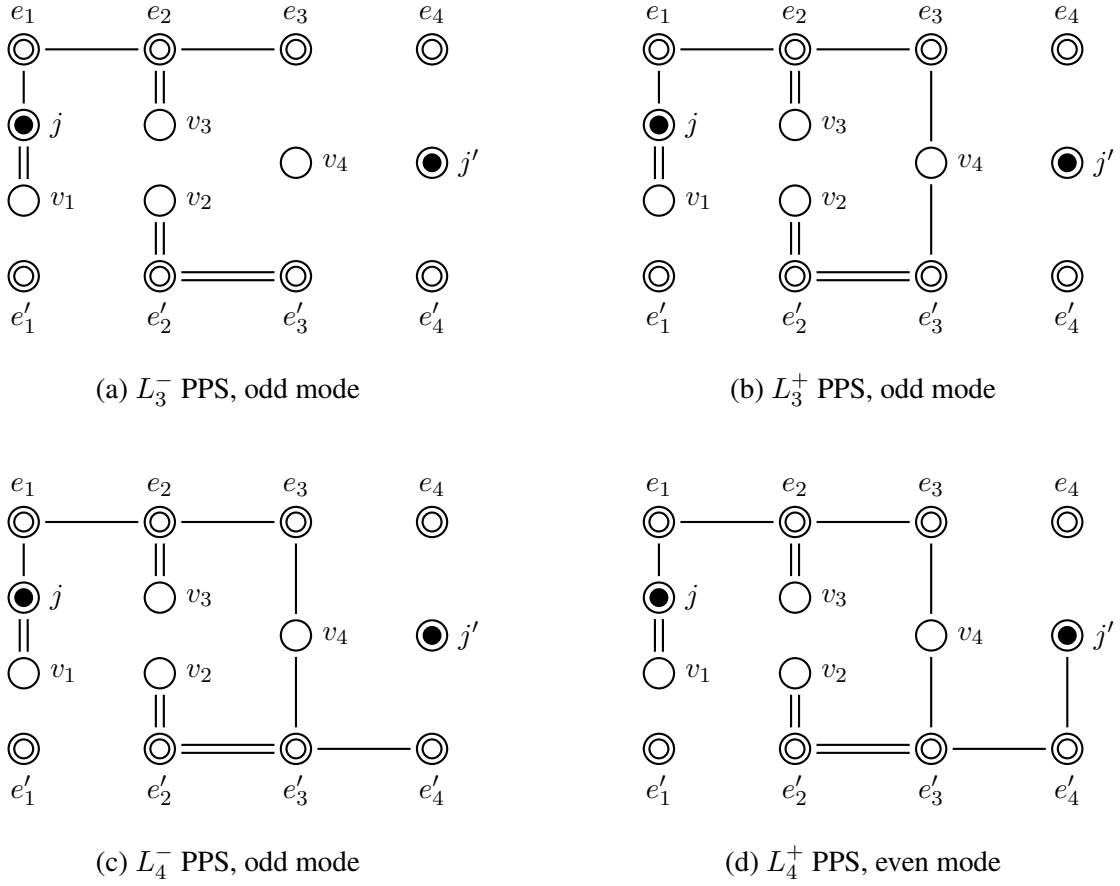

Figure 10: Mode examples for L_3 and L_4 PPSs in a warehouse with 4 aisles.

Proof of Theorem 3. To prove sufficiency of the conditions stated in Theorem 3, we show that a completion for any possible L_i PPS exists by following the schemes shown in Figure 11. The dashed parts are excluded for the completion of an L_i^+ PPS, and included for the completion of an L_i^- PPS. Figures (a)-(f) show completions for any L_i PPS of even mode, whereas (g) and (h) depict completions for any L_i PPS of odd mode. In (a)-(d), both end points are located to the right of aisle i . The completion schemes shown in (a) and (b) apply if the end points are located in different aisles, whereas (c) and (d) apply when the end points are located in the same aisle. (e) and (f) apply if both end points are located to the left of or within aisle i . There might be more or less aisles in the warehouse layout than depicted in the completion schemes in Figure 11. For aisles not shown in the schemes, a pair of parallel edges from the front to the rear of the aisle is inserted. To prove necessity, we suppose that $(T \subset L_i) \cup (T^c \subset R_i)$ forms a valid PS. Because no arcs in T are incident with vertices in T^c except for possibly e_i and e'_i , T cannot have a connected component which neither contains e_i nor e'_i . \square

Theorem 4 (Equivalence Conditions) Two PPSs T^1 and T^2 of L_i are equivalent if

1. both e_i and e'_i have the same degree parity (even, odd, or zero) in T^1 and T^2 ,
2. excluding vertices with zero degree, both T^1 and T^2 have the same number of connected components.

Proof of Theorem 4. Let $T^c \subset R_i$, such that $T^1 \cup T^c$ is a valid PS. Since e_i and e'_i have the same degree parity in both T^1 and T^2 , all vertices in $(T^2 \cup T^c) \setminus \{j, j'\}$ have even or zero degree, and j and j' have odd degree in $T^2 \cup T^c$. Contracting a connected component of a graph to a single vertex does not affect the connectivity of the graph. If we shrink the connected components of T^1 and T^2 in $T^1 \cup T^c$ and $T^2 \cup T^c$, the

(a)

(c)

(b)

resulting graphs are identical, namely, either T^1 and T^2 each shrink to a single vertex connected to e_i and e'_i in the same fashion or they each shrink to two vertices connected to e_i and e'_i in the same fashion. Therefore, because $T^1 \cup T^c$ is connected, $T^2 \cup T^c$ is also connected. It then follows from Theorem 2 that $T^2 \cup T^c$ is a valid PS. \square

Theorem 5 (Possible Equivalence Classes) Every possible L_i PPS belongs to one of a set C of 14 equivalence classes

$$C = \{000, 001, E01, 0E1, EE1, UU1, EE2, UU2, U01, 0U1, UE1, EU1, UE2, EU2\}. \quad (17)$$

Proof of Theorem 5. The set of all potential equivalence classes is formed by

$$\bar{C} = 000 \cup (\{0, E, U\} \times \{0, E, U\} \times \{1, 2\}). \quad (18)$$

Thus, there are $|\bar{C}| = 19$ potential equivalence classes. Without loss of generality, suppose a parallel-aisle warehouse layout with $r = 1$. For each equivalence class c in C , there is an edge configuration in Figure 5 which belongs to c when interpreted as an L_1^+ PPS. For example, Figure 5 (1) belongs to equivalence class UU1. The equivalence class which corresponds to each edge configuration can be read from the first row in Table 2.

It remains to show that equivalence classes 002, E02, 0E2, U02 and 0U2 are empty. To this end, we only need to note that if there are two components in a subgraph $T \subset L_i$ and at least one of vertices e_i and e'_i has zero degree, there is at least one component in T which neither connects to e_i nor e'_i . Thus, T does not meet requirement 4 of Theorem 3 for being an L_i PPS. \square

A.2 Theorems of Section 4.2

Lemma 1 (Maximum Vertex Degrees) A minimum length PS contains no more than two edges between any pair of vertices.

Proof of Lemma 1. Suppose a PS contains more than two edges between a pair of vertices v and v' . We construct a PS of shorter length the following way: remove two of the edges between v and v' as long as there are more than two edges between these vertices. Because the connectivity of the graph is preserved and removing an even number of edges between vertices v and v' does not change their degree parity, the resulting graph is still a valid PS. \square

A.3 Theorems of Section 4.4

Theorem 6 (Picking Path Construction Procedure) Given a valid PS, a picking path can be constructed by the following procedure:

1. Start at vertex j .
2. If there is a pair of unused parallel edges incident to the current vertex, use one of them to go to the next vertex, then continue with step 2.

3. If there are any unused single edges (i.e., not one of a pair of parallel edges), use one of them to go to the next vertex, then continue with step 2.
4. If there is a pair of parallel edges with one edge used and one edge still unused, use the unused edge to go to the next vertex, then continue with step 2.
5. Stop. Now the currently visited vertex is j' , and the order picking path is complete.

We prove the correctness of the procedure from Theorem 6 using the two following observations:

Corollary 2 (Incidence Patterns) *Given a valid PS of minimum length. As a consequence of Theorem 2 and Lemma 1, vertices j and j' are both incident with one single edge or with one single edge and two parallel edges, vertices P'_s are either incident with two single edges or two pairs of parallel edges, and vertices e_i and e'_i are either incident with two single edges, two single edges and a pair of parallel edges, two pairs of parallel edges, or three pairs of parallel edges.*

Lemma 4 (Path Subgraph Decomposition) *Let T be a valid PS of minimum length. Then T can be decomposed into a cycle-free path of single edges Π with start vertex j and end vertex j' and a set of cycles Θ such that $\Pi \cup \Theta = T$, where each cycle in Θ is of minimum length and connects to a single vertex in Π via a pair of parallel edges and each vertex in Π connects to at most one cycle from Θ .*

Proof of Lemma 4. Existence of Π can be proven inductively. From Corollary 2 it follows that j is connected to another vertex via a single edge. If this other vertex is j' , we have found the desired path. If this other vertex is not j' , it must be connected to yet another vertex via a single edge and so on. Π cannot have a cycle because a cycle with only single edges would imply that a vertex is incident with more than two single edges which violates Corollary 2.

If all edges in Π are removed from T , the degrees of j and j' are decreased by one, whereas the degrees of all other vertices in Π decrease by two. Hence, in the resulting graph, all vertices have even or zero degree, which means that all components in the remainder are Eulerian, i. e., they form a set of cycles. Because T is of minimum length, each cycle must be of minimum length.

Vertices j and j' are incident with one single edge, and all other vertices on Π are incident with two single edges. Thus, all cycles in Θ must connect to Π via a pair of parallel edges. Because of Corollary 2, each vertex in Π is incident with at most one pair of parallel edges, hence it connects to at most one cycle. \square

We can now prove the correctness of the procedure described in Theorem 6.

Proof of Theorem 6. The procedure starts at vertex $v' = j$, which by definition belongs to Π . As Lemma 4 states, every cycle in Ω connects to exactly one vertex in Π and we note that steps 2-4 in the procedure above are the same as in the construction procedure presented in Ratliff and Rosenthal (1983). Thus, if there is a cycle which connects to v' via a pair of parallel edges, the procedure will construct a subtour which starts and ends at v' while visiting all other vertices in the cycle. Now if $v' \neq j'$, the procedure advances to the next vertex on Π . \square

B Detailed results on benchmark instances

Tables 8–37 present the detailed results on the benchmark sets introduced in Section 6.1. We report for each instance the objective value f_0 when interpreting it as a traditional order picking problem instance and the

objective values f obtained by the different solution methods along with the respective runtime t in seconds when interpreting the instances as single-block WCTSP-GCS or WCTSP-OCS. We do not report objective values for CC for the WCTSP-GCS because they match those of DP on all instances. Underlined objective values denote optimal solutions. Table 38 shows the results of the heuristic picking policies (cp. Table 6) on the instance sets Centered Depot and Large Orders.

Table 8: Results on instance set Original with UDD and $l = 20$.
